Keywords:	Nitrous oxide, agricultural soils, emission inventory, flux upscaling, agricultural management, process-based model, temporal trend, spatial pattern
Abstract:	<p>China has experienced rapid agricultural development over recent decades, accompanied by increased fertilizer consumption in croplands, yet the trend and drivers of the associated nitrous oxide (N₂O) emissions remain uncertain. The primary sources of this uncertainty are the coarse spatial variation of activity data and the incomplete model representation of N₂O emissions in response to agricultural management. Here we provide new data-driven estimates of cropland N₂O emissions across China in 1990-2014, compiled using a global cropland-N₂O flux observation dataset, nationwide survey-based reconstruction of N-fertilization and irrigation, and an updated nonlinear model. In addition, we have evaluated the drivers behind changing cropland N₂O patterns using an index decomposition analysis approach. We find that China's annual cropland-N₂O emissions increased on average by 11.2 Gg N yr⁻² ($P < 0.001$) from 1990 to 2003, after which emissions plateaued until 2014 (2.8 Gg N yr⁻², $P = 0.02$), consistent with the output from an ensemble of process-based terrestrial biosphere models (TBMs). The slowdown of the increase in cropland-N₂O emissions after 2003 was pervasive across two thirds of China's sowing areas. This change was mainly driven by the nationwide reduction of N-fertilizer applied per area, partially due to the prevalence of the Nationwide Soil Testing and Formulation Fertilization Program that was launched in the early 2000s. This reduction has almost offset the N₂O emissions induced by policy-driven expansion of sowing areas, particularly in the Northeast Plain and the lower Yangtze River Basin. Our results underline the importance of high-resolution activity data and adoption of nonlinear model of N₂O emission for capturing cropland-N₂O emission changes. Improving the representation of policy interventions is also recommended for future projections.</p>

37 **ABSTRACT**

38 China has experienced rapid agricultural development over recent decades, accompanied by
39 increased fertilizer consumption in croplands, yet the trend and drivers of the associated nitrous
40 oxide (N₂O) emissions remain uncertain. The primary sources of this uncertainty are the coarse
41 spatial variation of activity data and the incomplete model representation of N₂O emissions in
42 response to agricultural management. Here we provide new data-driven estimates of cropland
43 N₂O emissions across China in 1990-2014, compiled using a global cropland-N₂O flux
44 observation dataset, nationwide survey-based reconstruction of N-fertilization and irrigation,
45 and an updated nonlinear model. In addition, we have evaluated the drivers behind changing
46 cropland N₂O patterns using an index decomposition analysis approach. We find that China's
47 annual cropland-N₂O emissions increased on average by 11.2 Gg N yr⁻² ($P < 0.001$) from 1990
48 to 2003, after which emissions plateaued until 2014 (2.8 Gg N yr⁻², $P = 0.02$), consistent with
49 the output from an ensemble of process-based terrestrial biosphere models (TBMs). The
50 slowdown of the increase in cropland-N₂O emissions after 2003 was pervasive across two
51 thirds of China's sowing areas. This change was mainly driven by the nationwide reduction of
52 N-fertilizer applied per area, partially due to the prevalence of the Nationwide Soil Testing and
53 Formulation Fertilization Program that was launched in the early 2000s. This reduction has
54 almost offset the N₂O emissions induced by policy-driven expansion of sowing areas,
55 particularly in the Northeast Plain and the lower Yangtze River Basin. Our results underline
56 the importance of high-resolution activity data and adoption of nonlinear model of N₂O
57 emission for capturing cropland-N₂O emission changes. Improving the representation of policy
58 interventions is also recommended for future projections.

For Review Only

61 **1. Introduction**

62 Nitrous oxide (N₂O) is a potent greenhouse gas, with a global warming potential 265~298 times
63 greater than that of CO₂ over a 100-year time horizon (Myhre et al., 2013). Its emissions are
64 recognized as the most important ozone-depleting substance (Ravishankara, Daniel, &
65 Portmann, 2009). Accumulating evidence points to croplands as the largest global source
66 (>40%) of anthropogenic N₂O (Paustian et al., 2016). Global cropland N₂O emissions are
67 projected to increase by ~50% from 2010 to 2050, due to the future intensification and
68 expansion of cropland production (Alexandratos & Bruinsma, 2012). Reducing cropland N₂O
69 emissions is a key mitigation option for limiting climate warming, especially in relation to
70 recently developed policy objectives relating to climate change and concerns regarding ozone
71 depletion (Allen et al. 2018). However, high spatial and temporal variability makes the
72 estimation of cropland N₂O emissions notoriously difficult (e.g., quantity, pattern, trend)
73 (Paustian et al., 2016), resulting in large discrepancies between bottom-up and top-down
74 approaches (Tian et al., 2016).

75

76 One of the sources of uncertainty is the model structure of bottom-up approaches that consider
77 a linear response of N₂O emissions to N application rate, as recommended in the Tier 1 method
78 for a national N₂O inventory by the Intergovernmental Panel on Climate Change (IPCC, 2006).
79 Recent synthesis of field observations suggests that N₂O emissions respond nonlinearly to an
80 increasing N application rate (Philibert, Loyce, & Makowski, 2012; Shcherbak, Millar, &
81 Robertson, 2014; Song et al. 2018) This nonlinear response was partially ascribed to the fact
82 that high ammonium ion concentrations from urea hydrolysis inhibits nitrite transformation to
83 nitrate (Ma, Shan, & Yan, 2015), resulting in nitrite accumulation which is subsequently
84 emitted as N₂O. Philibert et al. (2012) proposed a nonlinear model with fixed parameters, which
85 improved the predictive performance of N₂O flux. This model was further improved by using

86 random parameters from a more recent and a larger field observation dataset of N₂O flux
87 (Gerber et al., 2016). In addition to the nonlinear response of emissions to N inputs,
88 microbially-mediated N₂O is also strongly dependent on climate and soil properties (Perlman,
89 Hijmans, & Horwath, 2014). A spatially-referenced nonlinear model was therefore developed
90 to simulate N₂O emissions in response to fertilizer N application rate (N_{rate}) under various
91 environmental or management-related conditions (Zhou et al., 2015). Comparison between
92 models showed that such models outperformed nonlinear models with fixed or random
93 parameters (Zhou et al., 2015).

94

95 The accuracy of simulating N₂O emissions is dependent on the representation of model
96 parameters and the spatial aggregation of agricultural activity data. For example, a spatially-
97 referenced nonlinear model (Zhou et al., 2015) calibrated against observations in China was
98 able to better capture the variations of N₂O emissions on sites with similar conditions to the
99 calibration dataset, but was unable to reproduce emissions at other sites. To improve the
100 performance of diagnostic models at a regional scale, field observations representative of a
101 wide range of environmental and management-related variables are required. In addition, N₂O
102 emission models are sensitive to the degree of spatial aggregation in fertilizer and irrigation
103 data. Uncertainty of input data is expected to increase with decreasing spatial scale without
104 altering spatial differences in fertilizer and irrigation applications (Gerber et al., 2016).
105 Although the spatial resolution of management-related data is improving, mainly by evenly
106 disaggregating national-scale data into gridded maps (Lu & Tian, 2017; Zhang et al., 2017),
107 long-term, high-resolution maps of cropland-specific N-fertilizers and irrigation inputs are not
108 yet available at the global or regional scale.

109

110 China is currently the largest emitters of anthropogenic N₂O emissions globally (Zhou et al.,

111 2014). Over the past decades, this source in China increased with N-fertilizer use, accounting
112 for over 20% of global cropland-N₂O emissions from IPCC Tier 1 inventories (FAO, 2018;
113 Janssens-Maenhout et al., 2019; Winiwarter, Höglund-Isaksson, Klimont, Schöpp, & Amann,
114 2018). China is a large country with contrasting crop production systems, climate and soil types,
115 where the patterns of N₂O emissions are poorly understood compared to some developed
116 countries (Zou et al., 2010; Zhou et al., 2015; Yue et al., 2018). In the last decade, process-
117 based models (e.g., DNDC, DAYCENT, DLEM), used to produce Tier 3 IPCC estimates,
118 simulated global and regional cropland-N₂O emissions using sub-national N inputs from China
119 (Li et al, 2001; Tian et al., 2019; Yue et al., 2019). These models are arguably more realistic
120 than the Tier 1 approach because they account for climatic and soil variabilities. Although
121 multi-model ensemble may reduce some errors across individual models through a broader
122 integration of model processes (Tian et al., 2019), these individual models have rarely been
123 validated by observations across contrasting environmental and management-related
124 conditions (Ehrhardt et al., 2017), leading to large uncertainties not only in estimating emission
125 trends, but also in identifying underlying drivers.

126

127 To address these knowledge gaps, we re-estimate the spatial pattern and temporal trend of
128 cropland N₂O emissions across China in 1990-2014. We advance the estimation of spatially-
129 explicit, long-term cropland N₂O emissions in China by using an updated version of the
130 spatially-referenced nonlinear model (Zhou et al., 2015) with high-resolution, crop-specific
131 gridded datasets of N-fertilizer and irrigation uses. First, the model was updated through re-
132 calibration with N₂O emission observations three times more than previous dataset. Second,
133 maps (1-km) of crop-specific N-fertilization and irrigation application rates across Chin were
134 collated, based on a compilation of sub-national statistics or surveys (Zhou et al., 2014; Zou et
135 al. 2018), which differ from previous datasets based on downscaling of national totals (Lu &

136 Tian, 2017; Janssens-Maenhout et al., 2017) or modeling (Flörke, Schneider, & McDonald,
137 2018). Finally, using one type of index decomposition analysis (Ang, 2015), we separated the
138 contributions of agricultural management practices and environmental conditions on cropland
139 N₂O emission trends. This study considers direct emissions from croplands where synthetic
140 fertilizers, livestock manure, human excreta, and crop residues are added, as well as indirect
141 emissions due to atmospheric N deposition. Indirect emissions due to N leaching or runoff are
142 not considered.

143

144 **2. Data and methods**

145 **2.1 Updated spatially-referenced nonlinear model (SRNM)**

146 The previous version of the SRNM model (Zhou et al., 2015) assume a quadratic relationship
147 between cropland N application rates and N₂O emissions, with spatially-variable model
148 parameters depending on climate, soil properties, and crop management practices. The SRNM
149 predict cropland-N₂O emissions for each of geographical grids rather than administrative units.
150 This calibrated formulation of N₂O emissions was found to explain over 84% of the variance
151 of field observations (Zhou et al., 2015), yet the model was only constrained by 732 field
152 observations of N₂O emissions. We updated the model by fitting the N₂O emissions to new
153 observations extended to 2,740 flux observations across 345 sites in the world (see Text S1,
154 Tables S1~S2). The extended dataset covers a wider range of environmental conditions and
155 agricultural management practices compared to our previous work and other similar studies
156 (Gerber et al., 2016; Shcherbak et al., 2014) (Tables S3). The N₂O emissions (E) of the updated
157 SRNM model is described as:

$$158 \quad E_{ijt} = \alpha_{ij} R_{ijt}^2 + \beta_{ij} R_{ijt} + \gamma_{ij} + \varepsilon_{ijt}, \quad (1a)$$

159 where

$$160 \quad \alpha_{ij} \sim N\left(X_k^T \lambda_{ijk}, \sigma_{ijk}^2\right), \beta_{ij} \sim N\left(X_k^T \phi_{ijk}, \sigma_{ijk}^2\right), \gamma_{ij} \sim N\left(X_k^T \varphi_{ijk}, \sigma_{ijk}^2\right), \quad (1b)$$

$$161 \quad \lambda_{ijk} \sim N\left(\mu_{ijk}, \omega_{ijk}^2\right), \phi_{ijk} \sim N\left(\mu'_{ijk}, \omega'_{ijk}{}^2\right), \varphi_{ijk} \sim N\left(\mu''_{ijk}, \omega''_{ijk}{}^2\right), \varepsilon_{ijt} \sim N\left(0, \tau^2\right), \quad (1c)$$

162 and i denotes the sub-function of N₂O emissions ($i=1, 2, \dots, I$). j represents the type of crop
 163 ($j=1-9$, i.e., represents maize, wheat, paddy rice, vegetables, fruits, potatoes, oil crops, legume,
 164 and the other crops). k is the index of climate factors or soil property ($k=1-6$, i.e., soil organic
 165 carbon content, clay content, bulk density, soil pH, air temperature and the sum of precipitation
 166 and irrigation). E_{ijt} denotes the N₂O emission rate (kg N ha⁻¹ yr⁻¹) predicted for crop type j in
 167 year t in the i th type of regions. R_{ijt} is N application rate (kg N ha⁻¹ yr⁻¹). α , β , and γ are
 168 described as linear functions of climate or soil factors X_k (Table S2). γ is an intercept denoting
 169 the background emission, $\alpha R^2 + \beta R$ represents the fertilizer-induced emission, $\alpha R + \beta$ being the
 170 emission factor, and ε is the residual term. The random terms λ , ϕ , φ , and ε are assumed to be
 171 independent and normally distributed. μ is the mean applied N effect for α and β or the mean
 172 emission baseline for γ . σ , ω , and τ are standard deviations. All the parameter mean values and
 173 standard deviations in each of sub-functions were estimated by the Bayesian Recursive
 174 Regression Tree version 2 (BRRT v2) (Zhou et al., 2015), constrained by the extended dataset.
 175 The estimated parameter values are presented in Table S4. The detailed methodology of the
 176 BRRT v2 algorithm and the associated procedures can be found in Zhou et al. (2015).

177

178 2.2 New model inputs of N-fertilizers and irrigation

179 The updated SRNM model is forced by multiple gridded input datasets, including new datasets
 180 describing N inputs and irrigation to croplands. For N inputs, we first collected nationwide
 181 surveys of county-scale (the third-level administrative division) synthetic N fertilizer applied
 182 to croplands (F_{SN} , kg N yr⁻¹) for ~2900 counties in Mainland China, Taiwan, Hong Kong, and
 183 Macau for the period 1990-2014. These data were further disaggregated by nine types of crop,

184 based on the crop-specific, provincial data of R_{ijt} from the Statistics of Cost and Income of
185 Chinese Farm Produce (<http://tongji.cnki.net/overseas>). In addition, China has experienced
186 changes of County-scale administrative divisions, such as aggregation, disaggregation, and
187 name changes, so we harmonized the temporal evolution of F_{SN} to fit the latest administrative
188 divisions (<http://geodata.pku.edu.cn>), based on the historical trajectories summarized by the
189 Ministry of Civil Affairs of China (<http://xzqh.mca.gov.cn/>). More details can be found in Text
190 S2. Second, we estimated annual N in livestock manure, human excreta, and crop residues
191 returned to croplands by the *Eubolism* model at county scale (Chen, Chen, & Sun, 2010), based
192 on county-scale activity data, such as the numbers of livestock by animal, rural population, and
193 yields by crop type. The *Eubolism* model has been evaluated against multi-site observations in
194 highly-fertilized cropping areas across China (see Text S3). Third, dry and wet deposition of
195 N species were quantified by the global aerosol chemistry climate model LMDZ-OR-INCA at
196 a horizontal resolution of 1.27° latitude by 2.5° longitude (Wang et al., 2017), in which wet N
197 deposition fluxes have been validated by a recent global dataset (Vet et al., 2014). Finally, crop-
198 specific N application rates (R_{ijt}) were calculated as county-scale N input totals (i.e., synthetic
199 fertilizers, manure, human excreta, crop residues, and N depositions) divided by the associated
200 sowing areas that were obtained from the statistical yearbooks of 31 provinces
201 (<http://tongji.cnki.net/overseas>). This new county-scale dataset of R_{ijt} was then resampled into
202 a 1-km grid map based on the dynamic cropland distributions (Liu et al., 2014). We assumed
203 a maximum N fertilizer application rate of 700 kg N ha⁻¹ based on a previous study (Carlson
204 et al., 2017).

205

206 The second new gridded dataset is cropland irrigation application rate for the period 1990-2014.
207 We first collected prefectural-level (i.e., the second-level administrative division) cropland
208 irrigation amounts from two nationally-coordinated surveys: the 2nd National Water Resources

209 Assessment Program for the period 1990-2000 (China Renewable Energy Engineering Institute,
210 2014) and the Water Resources Bulletins of 31 provinces for the rest of period 2001-2014
211 (www.mwr.gov.cn/english/pubs/). Both surveys had an identical methodology, including
212 definitions, survey units, field surveys or measurements, and quality assurance. The detailed
213 survey methodology is described in Text S4. It should be noted that cropland irrigation used
214 here did not include water applied for aquaculture that accounts for less than 5% of agricultural
215 irrigation (Zhu, Li, Li, Pan, & Shi, 2013). Cropland irrigation rates (mm yr^{-1}) at the prefectural
216 level were then calculated as cropland irrigation amounts divided by sowing areas. Similarly
217 with R_{ijt} , these prefectural-scale cropland irrigation application rates were then disaggregated
218 by resampling to 1-km gridded cropland maps for the period 1990-2014, and such rates were
219 simply assumed same for each crop. Other data sources for model inputs can be found in Text
220 S5, including soil properties and climate factors relevant to N_2O emissions.

221

222 **2.3 Model validation and comparison**

223 Process-based models were run using the same input data, and their outputs were compared
224 with the results of the updated SRNM model. These process-based models include the Dynamic
225 Land Ecosystem Model (DLEM) (Tian et al., 2015), the Organising Carbon and Hydrology In
226 Dynamic Ecosystems (ORCHIDEE-OCN) (Zaehle & Friend, 2010), the Daily Century Model
227 (DAYCENT) (Del Grosso et al., 2009), and Vegetation-Integrated Simulator for Trace Gases
228 (VISIT) (Ito & Inatomi, 2012). Nitrification and denitrification processes in these models are
229 expressed as functions of available substrates (NH_4^+ or NO_3^- concentration), reaction rates,
230 soil temperature and water content, but with different formulations and parameterizations (Tian
231 et al., 2018). The results from atmospheric inversion of Saikawa et al. (2014), constrained by
232 global measurements of N_2O atmospheric concentrations, were also compared with the
233 estimated N_2O emissions. The new inversion was also conducted by replacing emissions from

234 this study for *a priori* agricultural soil emissions for China in the Bayesian inversion model
235 (Saikawa et al., 2014). The detailed methodology and parameter calibration of the process-
236 based models and the inversion model can be found in previous studies (Saikawa et al., 2014;
237 Tian et al., 2018). In addition, the national estimates of cropland N₂O emissions were compared
238 with the state-of-the-art emission inventories, including the Food and Agriculture Organization
239 Emission Database (FAOSTAT) (FAO, 2018), the Emissions Database for Global
240 Atmospheric Research (EDGAR version 4.3.2) (Janssens-Maenhout et al., 2019), and the
241 Greenhouse Gas and Air Pollution Interactions and Synergies (GAINS) (Winiwarter, Höglund-
242 Isaksson, Klimont, Schöpp, & Amann, 2018), U.S. Environmental Protection Agency (USEPA)
243 report (USEPA, 2012), and three China's National Communication Reports (CNCR; National
244 Development and Reform Commission, 2017) submitted to the UNFCCC for years 1994, 2005,
245 and 2012. Note that EDGAR, FAOSTAT and GAINS estimates were derived using the
246 methodology of the 2006 IPCC Guidelines for National Greenhouse Gas Inventories (IPCC,
247 2006) and national fertilizer data from the FAO.

248

249 **2.4 Attribution of N₂O emission trends**

250 We applied the Logarithmic Mean Divisia Index (LMDI) (Ang, 2015; Guan et al., 2018) to
251 attribute N₂O emission trends to different driving factors. The LMDI was chosen because of
252 its path independence, consistency in aggregation, and ability to handle zero values (Ang,
253 2015). The LMDI analysis compares a set of driving factors between the base and final year of
254 a given period, and explores the effects of these factors on the change in China's cropland-N₂O
255 emissions over that period. The detailed methodology of LMDI can be found in Ang (2015).
256 According to previous modeling studies (Guan et al., 2018), we decomposed cropland-N₂O
257 emissions into a combination of different drivers: total sowing area (A_k , ha), the share of nine
258 different crops to total sowing area (m_{jk} , %) also known as crop mix, N application rate (R_{jk} , kg

259 N ha⁻¹ yr⁻¹), and the emission intensity (e_{jk} , %) per crop type and region:

$$260 \quad E_k = \sum_j \left(A_k \times \frac{A_{jk}}{A_k} \times \frac{N_{jk}}{A_{jk}} \times \frac{E_{jk}}{N_{jk}} \right) = \sum_j (A_k \times m_{jk} \times R_{jk} \times e_{jk}), \quad (2)$$

261 where region $k=1-8$ corresponds to China, the Northwest, the Northeast Plain, the North China
 262 Plain, the lower reach of Yangtze River basin, the Southwest, the Northwest, and Qinghai-
 263 Tibet Plateau; A_{jk} is the sowing area of crop j in cropping region k ; N_{jk} and E_{jk} are N-fertilizer
 264 application amount and croplands N₂O emission of crop j in cropping region k , respectively. It
 265 should be noted that e_{jk} is defined as cropland-N₂O emission per unit of N_{jk} , which is different
 266 from the emission factor defined in the 2006 IPCC Guidelines, and represents the gross
 267 emission intensity at a given N application level. The change of E of region k in the year t
 268 compared to the year $t - 1$ is computed as

$$269 \quad \Delta E_k = \sum_j w_{jk} \ln \left(\frac{A_k^t}{A_k^{t-1}} \right) + \sum_j w_{jk} \ln \left(\frac{a_{jk}^t}{a_{jk}^{t-1}} \right) + \sum_j w_{jk} \ln \left(\frac{R_{jk}^t}{R_{jk}^{t-1}} \right) + \sum_j w_{jk} \ln \left(\frac{e_{jk}^t}{e_{jk}^{t-1}} \right). \quad (3)$$

$$= \Delta E_A + \Delta E_m + \Delta E_R + \Delta E_e$$

270 Here, $w_{jk} = (E_{jk}^t - E_{jk}^{t-1}) / (\ln E_{jk}^t - \ln E_{jk}^{t-1})$ is a weighting factor called the logarithmic mean
 271 weight (Ang, 2015). ΔE_A , ΔE_m , ΔE_R , and ΔE_e , are changes in E , corresponding to change in
 272 total sowing area, shift in crop mix, change in N application rate, and emission intensity,
 273 respectively. The change of ΔE between base and final years is then calculated by the
 274 cumulative ΔE between adjacent years. The sign of the ΔE indicates a positive or negative
 275 effect of the factor on the change of cropland N₂O emissions between the base and final years,
 276 and the potential impacts of nationwide policy interventions related to fertilizer application,
 277 crop type and sowing area.

278

279 **3. Results**

280 **3.1 Model performance**

281 Combining the new N inputs and irrigation data and the other forcing datasets with the updated
282 SRNM model, we estimated a mean annual N₂O emission from China's croplands of $0.62 \pm$
283 $0.06 \text{ Tg N yr}^{-1}$ during the period 1990-2014 (one standard deviation due to inter-annual
284 variability of N₂O emissions), with the spatial distribution shown in Fig. 1a. The validity of
285 our N₂O emission estimates was supported by internal cross-validation at 345 sites ($R^2=0.88$
286 and 0.90 for upland crops and paddy rice, respectively, Fig. 1b). In addition, our SRNM model
287 outputs performed well in reproducing the spatial contrast and long-term inter-annual
288 variability of N₂O emissions as well as the sensitivity of N₂O emission to environmental
289 changes (Figs S1 and S2). In addition, the N₂O emissions were corroborated against
290 independent simulations from four process-based models and the estimates from the
291 atmospheric inversion ($R^2 = 0.91$ and 0.66 , respectively, Fig. 1c). This new estimate of China's
292 cropland N₂O emissions is consistent with the USEPA report ($0.59 \text{ Tg N yr}^{-1}$) (USEPA, 2012),
293 and in general fell with the range of process-based models (0.35 to $0.73 \text{ Tg N yr}^{-1}$, Fig. 1c).
294 However, it exceeded emission estimates provided by EDGAR v4.3.2 product (Janssens-
295 Maenhout et al., 2017) by 43%, the FAOSTAT by +55%, the GAINS by 67%, and the CNCR
296 for years 1994 and 2005 by 36% (*t*-test at the 95% level, Fig. 1d), but was comparable to the
297 latest CNCR report for the year 2012 ($0.78 \text{ Tg N yr}^{-1}$).

298

299

300 **Figure 1. Validation of China's cropland N₂O emissions from the updated SRNM model.**
 301 (a) Pattern of mean annual N₂O emissions simulated (1990-2014). (b) Model performance of
 302 the simulated cropland N₂O fluxes. (c) Comparison of annual cropland N₂O emissions against
 303 the means of process-based models (1990-2014) and inversion models (1996-2008). Each point
 304 represents the estimated N₂O emissions from Chinese croplands for a certain year. Numbers in
 305 brackets show the number of models. (d) Comparison of annual cropland N₂O emissions with
 306 the emission inventories, including FAOSTAT (1990-2014), EDGAR v4.3.2 (1990-2012),
 307 CNCR (1994, 2005, 2012); USEPA (1990-2005), and GAINS (1990, 1995, 2000, 2005, 2010).
 308 Note that N, S, and R² denote the number of measurements, slope of regression line, and
 309 coefficient of determination, respectively.

310

311 **Figure 2. Comparisons of N inputs, emission factor and ‘background’ anthropogenic**
 312 **emissions of cropland N₂O in China.** (a) Synthetic fertilizers applied to croplands. (b) Other
 313 N inputs, including manure (M), crop residues (CR), human excreta (HE) returned to croplands,
 314 and atmospheric deposition (AD) over croplands. (c) Lognormal probability density function
 315 of emission factor for all upland crops based on gridded results during the period 1990-2014,
 316 where the dashed lines indicate the median values, and shaded areas represent standard
 317 deviation for this study and observed values (OBS) or 95% confidence interval for the IPCC
 318 and the CNCR. (d) Same as panel c but for paddy rice. (e) Same as panel c but for background
 319 emission (E^0) of upland rice. (d) Same as panel c but for E^0 of paddy rice. Note that the
 320 definition of FAOSTAT, IPCC, CNCR, and OBS can be found in the text.

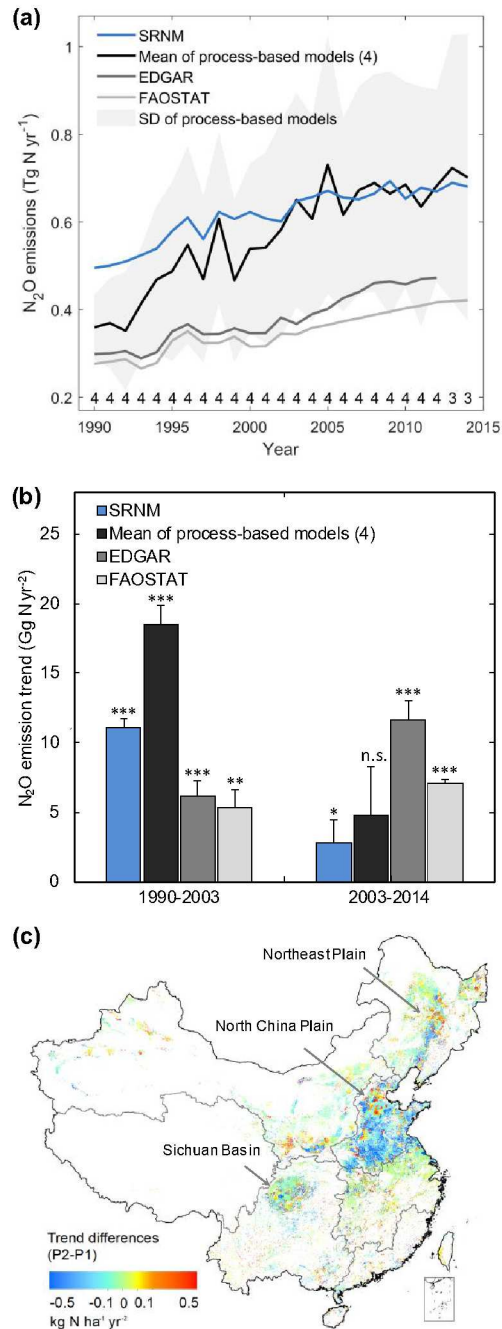

321

322 The differences between our estimates and other inventories were primarily attributed to the
323 updates of N input data, emission factors, and ‘background’ anthropogenic emissions from soil
324 residual N (Fig. 2). First, our county-scale estimation of synthetic N fertilizer application was
325 almost identical to the national statistics and FAOSTAT data (Fig. 2a), whereas the other N
326 inputs were substantially larger because the inclusion of human excretion and atmospheric
327 deposition over croplands (Figs 2b and S3). Second, our estimate of the nationally-averaged
328 N₂O emission factor (EF) for upland crops was larger than IPCC Tier 1 default by 20% (Fig.
329 2c), but the EF was -17% lower for paddy rice (Fig. 2d and Text S6). Furthermore, the
330 ‘background’ anthropogenic emissions of N₂O (γ) due to the legacy effect resulting from
331 historical soil N accumulation were estimated to be 1.40 ± 0.04 kg N ha⁻¹ yr⁻¹ for upland crops
332 and 1.30 ± 0.05 kg N ha⁻¹ yr⁻¹ for paddy rice in this study (Figs 2e and 2f), while they were not
333 fully accounted for by the IPCC Tier 1 inventories. Our estimates of this term were larger than
334 the values used in the CNCR (0.80 and 0.56 kg N ha⁻¹ yr⁻¹), but generally agreed with the *in*
335 *situ* observations (OBS) with zero N input (1.2 ± 1.2 and 1.0 ± 1.7 kg N ha⁻¹ yr⁻¹ based on 168
336 and 54 sites, respectively).

337

338 **3.2 Trend in cropland N₂O emissions in China**

339 Over the period 1990-2014, cropland N₂O emissions showed a persistent and widespread
340 increase (Fig. S4), because of the significant increase in N inputs to croplands. However, the
341 rate of this increase slowed down from 11.2 Gg N yr⁻² ($P < 0.001$) before 2003 to 2.8 Gg N
342 yr⁻² ($P = 0.02$) afterwards (Figs 3a and 3b), a turning point detected by Pettitt's test (Pettitt,
343 1979) ($P < 0.001$). This slower, insignificant growth of cropland-N₂O emissions was confirmed
344 by the process-based models with the same forcing datasets (19.8 Gg N yr⁻² for 1990-2003, P
345 < 0.001 ; 4.8 Gg N yr⁻² for 2003-2014, $P = 0.15$; Fig. 3b). We then divided the past 25 years
346 into two periods covering 1990-2003 (P1) and 2003-2014 (P2). Regionally,

347

348 **Figure 3. The inter-annual variability of cropland-N₂O emissions in China.** (a) Temporal
 349 evolution of annual cropland-N₂O emissions based on the updated SRNM model, an ensemble
 350 of four process-based models, and previous inventories (EDGAR v4.3.2 and **FAOSTAT**).
 351 Shaded area indicates the standard deviation of the results from process-based models.
 352 Numbers at the bottom show the number of process-based models available for each year. (b)
 353 Trends in cropland-N₂O emissions based on different approaches for two different periods (P1:
 354 1990-2003, P2: 2003-2014); ***, **, and * indicate significance of the trends at the 99.9%, 99%
 355 and 95% confidence interval, respectively; n.s., not significant. (c) Pattern of the difference in
 356 N₂O trends between the two periods.

357 approximately 64% of the Chinese sowing area experienced a weakened growth or even a
358 decline of N₂O emissions in P2, primarily located in major cropping areas such as the North
359 China Plain, the Sichuan Basin, and a part of the Northeast Plain (Fig. 3c), while the rest
360 showed a growth in emissions, mainly in Heilongjiang province and the Northwest China (Fig.
361 3c). By contrast, the estimates provided by EDGAR v4.3.2 have suggested enhanced growth
362 of cropland-N₂O emissions across China (Figs 3b and S5). The estimated growth rate of
363 cropland-N₂O emissions in EDGAR v4.3.2 after 2003 (11.6 Gg N yr⁻², $P < 0.001$) is much
364 larger than that for 1990-2003 (6.2 Gg N yr⁻², $P < 0.001$; Fig. 3b). Differences in emission
365 trends between our estimates and the EDGAR product are mainly focused around the North
366 China Plain (Fig. S5).

367

368 **3.3 Drivers of China's cropland-N₂O emission trends**

369 The decomposition analysis in Fig. 4 shows the contribution of each of the four drivers to the
370 change in cropland-N₂O emissions in China and its seven major cropping regions. For P1, the
371 trend of emissions was associated with a growth of N_{rate} for all crops (Fig. 4a), mainly located
372 in the North China Plain and the Northeast Plain (Figs 4c-4d). For P2, the slower growth in
373 cropland-N₂O emissions across China was driven by the downward influences from the
374 reduced N_{rate} and emission intensities, which largely offset the strong expansion of sowing
375 areas particularly in the Northeast Plain (Figs 4a and 4c). By contrast, the shifts in the crop mix
376 and in emission intensity contributed marginally to changes in emissions in both periods (Fig.
377 4a).

378

379 Contributions of the four driving factors to cropland-N₂O emission trends differed between
380 cropping regions (Figs 4b-4h). During the period P1, the trend in cropland-N₂O emissions was
381 explained by the growth of N_{rate} in most of the major cropping regions, except for the Northwest

382 where there was decreased emission intensity. During the period P2, sowing area expansion
 383 became the largest contributor to the positive cropland-N₂O emission trends in the Northeast
 384 Plain, the Northwest, the Southwest, as well as the lower reaches of the Yangtze River basin.
 385 However, the decrease in emission intensity dominated the change in cropland-N₂O emissions
 386 in the North China Plain, and N_{rate} contributed to the changes in the Southeast and Qinghai-
 387 Tibet Plateau.

388 **Figure 4. Contribution of different drivers to the change in cropland-N₂O emissions by**
 389 **cropping region during 1990-2003 (P1) and 2003-2014 (P2).** a. China; b. northwest China;
 391 c. northeast China; d. North China Plain; e. lower Yangtze Basin; f. southeast China; g.
 392 southwest China; h. Qinghai-Tibet Plateau. Note varying vertical-axes. The length of each bar
 393 reflects the contribution of each factor during the corresponding period.

394

395

cropping regions. **b.** N_{rate} by crops. **c.** National sowing areas and county number applied by the

Nationwide Soil Testing and Formulation Fertilization Program. **d.** National sowing areas by

crops. **e.** Provincial areas and ratio of croplands using mechanically-aided deep placement of

fertilizers in 2003 and 2014, where the ratio is calculated as the croplands using this technology

divided by national cropland area. **f.** Same as panel e but for crop residues returned to croplands.

The seven cropping regions include Southeast (SE), Southwest (SW), Lower Yangtze Basin

(LYB), Qinghai-Tibet Plateau (Q-T), North China Plain (NCP), Northeast (NE) and Northwest

(NW). HLJ: Heilongjiang, IM: Inner Mongolia, JL: Jilin, XJ: Xinjiang, HN: Henan, LN:

Liaoning, HB: Hebei, SX: Shanxi, SD: Shandong, AH: Anhui, JS: Jiangsu

Overall, in period P2 (after 2003), the reduction of N_{rate} dominated the slowdown of cropland-

N_2O emissions in China. According to nationwide statistics, China's N_{rate} showed a clear

reduction in period P2 (after 2003), the reduction of N_{rate} dominated the slowdown of cropland-

N_2O emissions in China. According to nationwide statistics, China's N_{rate} showed a clear

reduction in period P2 (after 2003), the reduction of N_{rate} dominated the slowdown of cropland-

N_2O emissions in China. According to nationwide statistics, China's N_{rate} showed a clear

reduction in period P2 (after 2003), the reduction of N_{rate} dominated the slowdown of cropland-

408 reversal in trend around 2003, from an increasing rate of $+5.1 \text{ kg N ha}^{-1} \text{ yr}^{-2}$ in P1 to a decrease
409 of $-0.7 \text{ kg N ha}^{-1} \text{ yr}^{-2}$ in P2, although it varied across different cropping regions (Fig. 5a).
410 Similar decreases in crop-specific N_{rate} were found for wheat, maize, and paddy rice, but not
411 for vegetables and fruits, all with Pettitt's test (Fig. 5b, $p < 0.001$). Interestingly, these change
412 points were, in general, coincident with changes in cropland- N_2O emissions in China. The
413 reductions of N_{rate} were mainly due to declines in synthetic fertilizer uses, particularly in the
414 eastern and central China, the Yunnan-Guizhou Plateau, and the North China Plain (Fig. S6).

415

416 **4. Discussion**

417 Reliable estimation of cropland- N_2O emissions and their drivers is fundamental to the
418 development of policy for sustainable N management. Previous estimates have shown large
419 differences in the magnitude and temporal evolution of annual cropland- N_2O emissions. This
420 has mainly been due to the lack of high-resolution data on agricultural management and of
421 spatial representation in the models. Our updated SRNM model, along with new, crop-specific
422 gridded datasets of N inputs and irrigation, permits a new insight into the spatial contrast and
423 inter-annual variability of cropland- N_2O emissions, and associates these with policy-driven
424 technological adoption and environmental changes.

425

426 The reduced N_{rate} suggests that national N use efficiency of fertilizers has improved over recent
427 decades, given that there was no reduction in per-area crop yields according to the national
428 statistics (Sun & Huang, 2012). One of the most effective methods of making fertilizer use
429 more efficient is to match the supply of nutrients with demand during field application
430 (Richards et al., 2015). Such an approach was one of targets of the Nationwide Soil Testing
431 and Formulation Fertilization Program, launched in the early 2000s (Table S7). This program
432 started with staple crops, which account for $\sim 50\%$ of national N inputs on average, but after

433 2010 it extended to a number of cash crops. These improved N use efficiencies for staple crops
434 were also found in the most recent study (Zou et al., 2018). According to national statistics
435 (Sun & Huang, 2012), such technologies increased in prevalence on croplands from 3.3 million
436 ha in 200 counties, to ~93 million ha in 2,498 counties (Fig. 5c). In addition, spatial re-
437 allocation of crops has extensively happened in China over recent decades, and is characterized
438 by an emerging shift from peri-urban areas in the South and Central China (high N rate) to rural
439 areas in the North (low N rate) because of urbanization (Fig. S7; Zou et al., 2018). Although
440 the effectiveness of the Nationwide Soil Testing and Formulation Fertilization Program on the
441 N_{rate} is difficult to quantify at the regional scale, these measures contributed to the decline in
442 N_{rate} across China (Chen et al., 2014).

443

444 The increased sowing area was identified as the second important driver of cropland- N_2O
445 emission trends in P2 that partially offset the effect of decreasing N_{rate} . The shift in crop mix
446 resulted in positive emission trends in P1, but made negligible contributions across most
447 cropping regions in P2. Specifically, sowing areas by crop have changed in line with multiple
448 nationwide crop structural transition programs in China. During the period 1990-2003, the
449 Government of China encouraged the growth of cash crops to meet increased consumption
450 requirements. According to national statistics, the sowing areas of vegetables and fruits
451 increased by 115% and 57% in the P1 (Fig. 5d), respectively. Meanwhile, the areas sown to
452 wheat and paddy rice declined by -30% and -22%, and sowing area of maize remained at the
453 level as that in 1990. This structural transition in cropping patterns that occurred in P1 resulted
454 in more cropland- N_2O emissions, because vegetables and fruits, which constitute the major
455 area of cash crops, have an emission factor two times higher than that of staple crops (Dobbie
456 & Smith, 2003). During P2 (after 2003), the Government of China aimed to stabilize the
457 production of cash crops, but to also restore the production of cereal crops. As a result, the

458 sowing areas of staple crops increased by 36%, while the sowing areas of vegetables, fruits,
459 and oil crops were increased by only 11% (Fig. 5d). Compared to the period P1, this shift in
460 crop mix in P2 exerted a lower upward pressure on cropland-N₂O emissions, particularly in the
461 major cropping regions. The results underscore the significance of land-use changes to the
462 spatial and inter-annual variabilities of N₂O emissions.

463

464 Our results show that emission intensity decreased during both periods and had a negative
465 effect on the growth of cropland-N₂O emissions across most of the cropping regions. Scenario
466 simulations based on the SRNM (see Text S7) suggest that N_{rate} was the dominant factor
467 controlling the emission intensity trend, followed by soil organic carbon (SOC) and water
468 inputs (Fig. S8). Increased SOC offset 19% and 51% of the negative effects from N_{rate} for P1
469 and P2, respectively. Thus whilst C sequestration can help offset some of the cropland
470 emissions of CO₂, a recent study suggests that carbon emission equivalents of non-CO₂ GHG
471 emissions are currently ~12 times greater than carbon uptake by Chinese croplands over 100-
472 year time horizon (B. Gao et al., 2018). SOC also played a role in increasing N₂O emissions
473 with a positive correlation between N₂O emissions and SOC reported in field (Figueiredo,
474 Enrich - Prast, & Rütting, 2016), laboratory studies (Jäger, Stange, Ludwig, & Flessa, 2011),
475 meta-analyses (Bouwman, Boumans, & Batjes, 2002; Charles et al., 2017), and data mining
476 analysis (Perlman et al., 2014). The positive effect of SOC could be explained by high SOC
477 providing sources of energy, C and N for nitrifying and denitrifying microorganisms, and
478 creating anaerobic conditions favoring the oxidation-reduction reaction for denitrification
479 (Charles et al., 2017).

480

481 At present, the attribution of trends in cropland-N₂O emissions to driving factors contains some
482 uncertainties. Other potential factors responsible for the decline in emissions seem also to be

483 important, but were difficult to consider explicitly. These include, among others, changes in
484 crop cultivars (Zhang, Fan, Wang, & Shen, 2009), cultivation technology improvements places
485 (Jiang et al., 2018), timing (Jiang et al., 2018; Wang et al., 2016) and placement methods (Chen,
486 Wang, Liu, Lu, & Zhou, 2016), and changes in fertilizer type (Bouwman et al., 2002). For
487 example, multiple field trials for staple crops in China suggest a significant increase in N-use
488 efficiency (ratio of yield to N_{rate}) associated with cultivar improvement over recent decades (de
489 Dorlodot et al., 2007). However, this does not mean a coincident reduction of N_{rate} because
490 crop yields (i.e., per-area crop production of these new cultivars) grew synergistically, and thus
491 might require more fertilizer per unit of cropped area. The improvement of cultivation
492 technology plays an important role in influencing cropland- N_2O emissions. For example, the
493 proportion of croplands using mechanically-aided deep placement of fertilizers increased from
494 11% in 2003 to 26% at present, particularly in the north of China (Fig. 5e), decreasing the N
495 losses and thereby cropland- N_2O emissions. Increasing the return of crop residues, also
496 particularly in the North China Plain, has been hypothesized as an emerging driver for the
497 change of N_{rate} . In these regions, crop residues returned to croplands accounted for from 21%
498 in 2003 to 33% of croplands in 2014 (Fig. 5f), increasing the potential to replace the application
499 of synthetic fertilizers, and to change carbon and N biogeochemical cycles in soils (Chen, Li,
500 Hu, & Shi, 2013; Xia et al., 2018). However, the effect of crop residues on cropland- N_2O
501 emissions is more complex and modified by the prevalence of aerobic and anaerobic soil
502 conditions (Xia et al., 2018), and also the chemical composition of the plant material (S. Gao
503 et al., 2018).

504

505 In summary, the results from this study underline the advantage of high-resolution agricultural
506 activity data and emission intensity detailed by crop type, land-use dynamics and technology
507 improvement to understand the change in cropland- N_2O emissions. Most of the state-of-the-art

508 emission inventories that aim to quantify global N₂O emissions, fail to capture either the
509 magnitude or temporal trends in China. This is because firstly, an IPCC default EF of 1%
510 assumes a constant relationship between N input and N₂O emissions. This cannot reproduce
511 the spatial and temporal responses of N₂O emission to environmental changes. Secondly,
512 emission inventories, in general, disaggregate national-scale or low-resolution fertilizer and
513 irrigation data into gridded maps to generate cropland-N₂O emission patterns. This would be
514 likely to lower emission estimates from regions predominantly fertilized at high N inputs (e.g.,
515 the North China Plain), while increasing emission estimates from under-fertilized areas (e.g.,
516 the Northeast Plain). Process-based terrestrial biosphere models (TBM) still face many
517 challenges in modelling changes in cropland-N₂O emissions (Sandor et al. 2018). Though most
518 of them consider the biotic and abiotic processes involved N₂O production, they also generate
519 divergent estimates of cropland-N₂O emissions and spatio-temporal patterns (Tian et al., 2018).
520 Possible reasons for divergent estimates among TBMs are the incomplete model representation
521 of N₂O emissions in response to agricultural management practices and uniform response
522 functions of the N₂O flux to environmental conditions (e.g., SOC). Improving the
523 representation of crop-specific agricultural activity data and the regional adoptions of N₂O flux
524 response are recommended for future projections.

525

526 The updated SRNM model for China's cropland-N₂O emissions could be extended to other
527 countries for updating their cumulative emissions and their contributions to global historical
528 radiative forcing and ozone depletion. The decomposition of cropland-N₂O emission trends to
529 underlying drivers could facilitate the tracking of key indicators that require significant change.
530 Our modeling results also highlight that technological adoption was intertwined with policy
531 interventions in China. We argue that designing more realistic future scenarios for
532 technological adoption will increase the likelihood that policies will be implemented to set

533 targets and incentives for cropland-N₂O emission mitigation.
