Background: Combined ICS and long-acting bronchodilators (LABD) more effectively reduce COPD exacerbations than LABD therapy alone. Corticosteroid-related adverse effects, including pneumonia, limit ICS use. Previous data suggest this risk is lower for extrafine beclometasone (ef-BDP). We compared pneumonia risk among new users of fixed dose ICS/LABD formulations containing ef-BDP, versus patients initiating LABD without any ICS.

Methods: A propensity-matched historical cohort study design used data from OPCR. COPD patients with ≥ 1 year of continuous data who initiated LABD or ICS/LABD formulations containing ef-BDP were matched. Primary outcome was time to pneumonia event, as treated, using either sensitive (physician diagnosed) or specific (physician diagnosed and x-ray or hospital admission confirmed) definitions, with non-inferiority boundary of 15%.

Results: 23,898 COPD patients were matched, who were 68 ± 11 years, 54.3% male and 56% current-smokers, while 43% were former-smokers. Initiation of ef-BDP/LABD was not associated with an increased risk of pneumonia versus LABD, for either a sensitive 0.89 (0.78–1.02), $P = 0.08$ or a specific 0.91 (0.78–1.05), $P = 0.18$ definition of pneumonia. The probability of remaining pneumonia free 1-year after ef-BDP/LABD was 98.4%, which was comparable to LABD at 97.7%, and was sustained up to 6 years of observation; non-inferiority criterion was met for both definitions. Initiation of ef-BDP/LABD was also associated with a reduced risk of developing LRTIs in the propensity matched cohort.

Conclusion: Risk of pneumonia when using ICS for the management of COPD reported in several randomised controlled trials may not be relevant with ef-BDP in a diverse real-world clinical population.

Keywords: inhaled corticosteroids, pneumonia, COPD, extrafine beclometasone, long-acting bronchodilators

Introduction

Inhaled long-acting bronchodilators (LABD) include both long-acting beta agonists (LABA) and long-acting muscarinic antagonists (LAMA).¹ LABD use in COPD has been shown to improve lung function, dyspnoea, health status and reduce exacerbations rates.² In patients who experience frequent or moderate to severe exacerbations, inhaled corticosteroids (ICS) can be combined with LABD, forming either a double or triple therapy.^{1,2}

The use of a double therapy containing ICS and LABA has been shown to be more effective than each component in isolation in improving lung function, symptoms and quality of life and reducing exacerbations and their severity and is a commonly used first line treatment for symptomatic patients at risk of exacerbations, especially in those with high blood eosinophil levels.^{3–11} In the most recent GOLD 2023 iteration, triple therapy with ICS/LABA/LAMA is the preferred treatment of choice in COPD patients that require ICS, particularly with the following thresholds of blood eosinophils: >100 cells/mL - Favors use; >300 cells/mL - Strongly favors use. At these eosinophil thresholds, ICS/LABA/LAMA triple therapy is more effective for reducing exacerbations when compared to combined LABD therapy.^{2,12} Further, two large one-year randomized controlled trials (IMPACT and ETHOS) provide new evidence on mortality reduction with fixed-dose inhaled triple combinations compared to dual bronchodilation,² so triple therapy is recommended for patients whose dyspnoea and exacerbations are not managed on dual regimes.^{2,13}

The superior effects of ICS-containing dual and triple therapies in improving COPD outcomes, when compared to each component in isolation have mostly been attributed to their anti-inflammatory effects.^{14–16} Despite the benefits of ICS, there are risks, among the most notable being an increased incidence of pneumonia that is associated with regular ICS use.^{5,16–23} However, COPD itself is a significant risk factor for the development of pneumonia,^{24,25} and this is further magnified for patients aged 55 years and older, with severe airflow limitation ($FEV_1 < 50\%$ predicted), a history of prior COPD exacerbations, a poor modified medical research council (mMRC) dyspnoea score, low body mass index²⁶ and comorbid conditions.²⁷ ICS should also be used with caution in COPD patients with a prior history of pneumonias.²⁸

Recent observations suggest not all ICS carry the same pneumonia risk, and subclass variations may exist. For example, in the PATHOS and UPLIFT studies, patients using fluticasone propionate containing formulations had an increased risk of developing pneumonia when compared to therapies containing other ICS compounds.^{20,28} More specifically, the use of fluticasone propionate/salmeterol in COPD patients has been associated with an increased risk of pneumonia and severe exacerbations when compared to budesonide/formoterol or beclometasone/formoterol in a retrospective cohort study.^{29,30} Similarly, a recent meta-analysis suggests the use of fluticasone containing formulations in COPD are linked to an increased pneumonia risk (greater with fluticasone propionate than with fluticasone furoate) which was not observed when using budesonide or beclometasone.³¹ However, these apparent differences between ICS in terms of pneumonia risk may relate to other factors including patients' characteristics, diagnostic criteria for pneumonia, or different study designs.

In highlighting these observations, it should be acknowledged that, irrespective of subtype, the use of an ICS containing formulation may carry an increased risk of pneumonia compared to LABD without ICS, as evidenced in the ETHOS, TRINITY, FORWARD and IMPACT studies.^{21,32–34} A notable exception is the TRIBUTE study, which directly compared extrafine beclometasone-glycopyrronium-formoterol in a single inhaler with glycopyrronium-indacaterol, and showed no difference in the risk of pneumonia over 12 months in patients with severe symptomatic COPD who were at risk of exacerbations.³⁵

Notably, the above reported studies were randomised controlled trials (RCTs) and the pneumonia risk associated with ICS use were reported as adverse outcomes. Thus, they utilised a select, non-real-world cohort of participants and were not designed or necessarily powered to detect the true risk of ICS use association with pneumonia in a real-world population of COPD patients. Previous real-world studies suggested that extra-fine particle formulations of ICS may be associated with lower risk of pneumonia than with other fine-particle formulations, which may relate to differences in lung deposition.^{36,37} Therefore it would be of interest to assess the risk of pneumonia in a broad real-world matched population of COPD patients who are utilising either ICS/LABD formulations or LABD therapies without ICS. Doing so would enable assessment of pneumonia risk in a large clinical population of COPD patients with diversity in age, comorbidities, risk factors and disease severity, which is different to the homogeneous populations normally incorporated

in RCTs. Additionally, the use of a uniform definition of pneumonia would also be advantageous. The aim of the present investigation was to compare the risk of pneumonia in COPD patients who are new users of fixed dose ICS/LABD formulations containing extrafine beclometasone (ef-BDP), administered as either a dual or triple therapy, versus patients initiating LABD, either as mono or dual LABA/LAMA therapy.

Methods

Study Design and Ethical Approval

A historical propensity matched cohort study, including a broad real-life population of patients with active COPD in the UK was conducted. The baseline, reference period was one year prior to the index date, which was defined as the initiation date of either a dual or triple ICS/LABD formulation containing ef-BDP, or either mono or dual LABD therapy containing a LABA and/or a LAMA. Data was obtained from the Optimum Patient Care Research Database (OPCRD), which comprises electronic medical records from over 12 million patients and allows for a long retrospective period, with the median time in the database being 13 years and a large proportion having summary medical data from birth. Data were restricted from 2014 onwards. Additionally, the respiratory-related measures contained within the database have been validated using patient reported outcomes. OPCRD has ethical approval from the National Health Service Research Authority to hold and process anonymised research data (Research Ethics Committee reference: 15/EM/0150).

The protocol for the current investigation was established prior to data extraction and was performed in accordance with the European Network of Centers for Pharmacoepidemiology and Pharmacovigilance (ENCePP) code of conduct (2014). The study was also registered with the European Union electronic Register of Post-Authorisation studies (EUPAS35439) and approval was granted by the Anonymised Data Ethics Protocols and Transparency committee, the independent scientific advisory committee for OPCRD (ADEPT0820).

Inclusion and Exclusion Criteria

To be eligible for inclusion, patients were required to be 40 years of age or older at the time of COPD diagnosis, have >1 year of continuous data within their electronic medical record prior to the index date and be commencing either a dual or triple ICS/LABD formulation containing ef-BDP (Foster[®] and Trimbow[®]) or a mono or dual LABD therapy (either LAMA, LABA or LAMA/LABA). Patients were also required to have no history of using the class of formulation (ie no ICS before) that they were commencing and were required to have a second prescription of the same medication within 90 days of the first, to avoid brief treatment trials and patients with only temporary medical records.

Exclusion criteria for the current investigation were having a smoking status of “never smoked” or a diagnostic read code for asthma or any other chronic lower respiratory tract condition other than COPD. A diagnosis of bronchiectasis was not established as an exclusion criterion as it is often misdiagnosed and a frequent comorbidity of COPD. Any patients who experienced a pneumonia event or respiratory related bacterial infection in the 28 days prior to the index date also had their medical records excluded.

Outcomes

The primary outcome was time to first pneumonia event, using either a sensitive or a specific definition. A sensitive definition pneumonia was defined as any pneumonia diagnosed by a physician, and a specific definition pneumonia was defined as physician diagnosed pneumonia that was confirmed with a chest radiograph or hospital admission within one month of diagnosis. The secondary outcome was time to first lower respiratory tract infection (LRTI), which was defined as needing an antibiotic prescription with evidence of a LRTI on the same day. A full list of diagnostic READ codes used to define LRTI is available upon request. Exploratory analyses were also conducted to allow for more comprehensive comparisons of the harm related to these treatment regimens. This included the time to first event for acute oral corticosteroid use, antibiotics prescription, exacerbation, primary care recorded hospitalisation and pneumonia-related hospitalisation.

Confounders and Propensity Matching

Full details of the 1:1 matching process are provided in [Appendix 1](#). Briefly, inclusion in the matching process required a covariate to have no more than 20% missing data. The propensity score was generated from logistic regression modelling using all available patient-level baseline characteristics that were expected on clinical grounds to be related to the outcome or to both the outcome and treatment allocation. The logit of the propensity score was used as the matching scale with a calliper width equal to 0.2 of the standard deviation of the logit of the propensity score, in line with the recommendations of Austin.³⁸

Matching rate and multivariable balance were used to establish criteria for accepting a matching set. Residual bias potential after propensity matching was assessed and if bias statistics were at least 2%, baseline variables were added to the outcome model in a forward selection approach, in descending order of highest bias potential.

Statistical Analysis

Non-inferiority of ef-BDP/LABD formulations was assessed against LABD using per protocol analysis. The upper boundary of non-inferiority was a relative difference of 15% corresponding to a hazard ratio at or below 1.15, with the non-inferiority boundary based on a prior randomised controlled trial comparing fluticasone with salmeterol⁵ and triple therapy containing fluticasone with double bronchodilation.³³ The increased risk associated with ICS use in COPD patients was not an expected finding by Calverley et al,⁵ as such there was no prospective definition of pneumonia in this study. Lipson et al³³ however, defined a pneumonia event as a physician diagnosis considering cough, sputum purulence, dyspnoea, physical examination findings and laboratory results, but also required a chest radiograph to be obtained. In the current investigation, patients were censored at the end of data availability, either when leaving the practice or last time data was extracted or on changes to medication regime.

Cox regression was used for time to event analysis. In the primary analysis, this allowed for the assessment of the association between ICS treatment and time to the first pneumonia event following initiation of an ef-BDP/LABD or LABD. Analyses were repeated in unmatched and propensity score matched samples to quantify the impact of measured confounders. To minimise residual confounding, a doubly robust approach was adopted in which the Cox regression models were adjusted for baseline characteristics with bias statistics of at least 2% in propensity score matched samples ([Appendix 2](#)). A similar approach was adopted for the secondary and exploratory outcomes. Exacerbations occurring within 28 days of a previous event were considered part of a single episode. From this modelling, hazard ratios and 95% confidence intervals for each effect were generated. All statistical analysis was performed using R,³⁹ with propensity score matching performed using the Matching package.³⁷

Results

Comparison of ef-BDP and LABD Populations

A total of 54,400 patients were eligible for inclusion, 13,485 commencing an ef-BDP containing ICS/LABD and 40,915 commencing LABD ([Figure 1](#)). Of these 23,898 patients were matched, that is 11,949 commencing an ef-BDP based ICS/LABD formulation and 11,949 commencing LABD. Baseline characteristics of the unmatched and propensity matched cohorts for new users of ef-BDP/LABD and LABD are shown in [Table 1](#) and [Appendix 2](#). Prior to matching, the ef-BDP/LABD cohort had more severe COPD in comparison to the LABD cohort, as indicated by exacerbations, FEV1% and mMRC scores. Following the matching process, irrespective of the cohort, patients were most likely to have experienced ≤ 1 exacerbations in the previous year, have an FEV1% between 50–80% of predicted value and have an mMRC score of ≥ 2 . The distribution of propensity scores had a broad region of common support ($0.03 < \text{propensity score} < 0.97$) ([Figure 2](#)) and the standardized mean difference was below the 10% threshold for all baseline characteristics, signifying sufficient balance between groups ([Figure 3](#)). In particular, both groups of patients were 68 ± 11 years, 54.3% were male, and 56% were current-smokers while 43% were former-smokers. By design, both groups were also equally balanced by BMI, blood eosinophils, GOLD stage, FEV1% predicted and mMRC score (all $p > 0.05$).

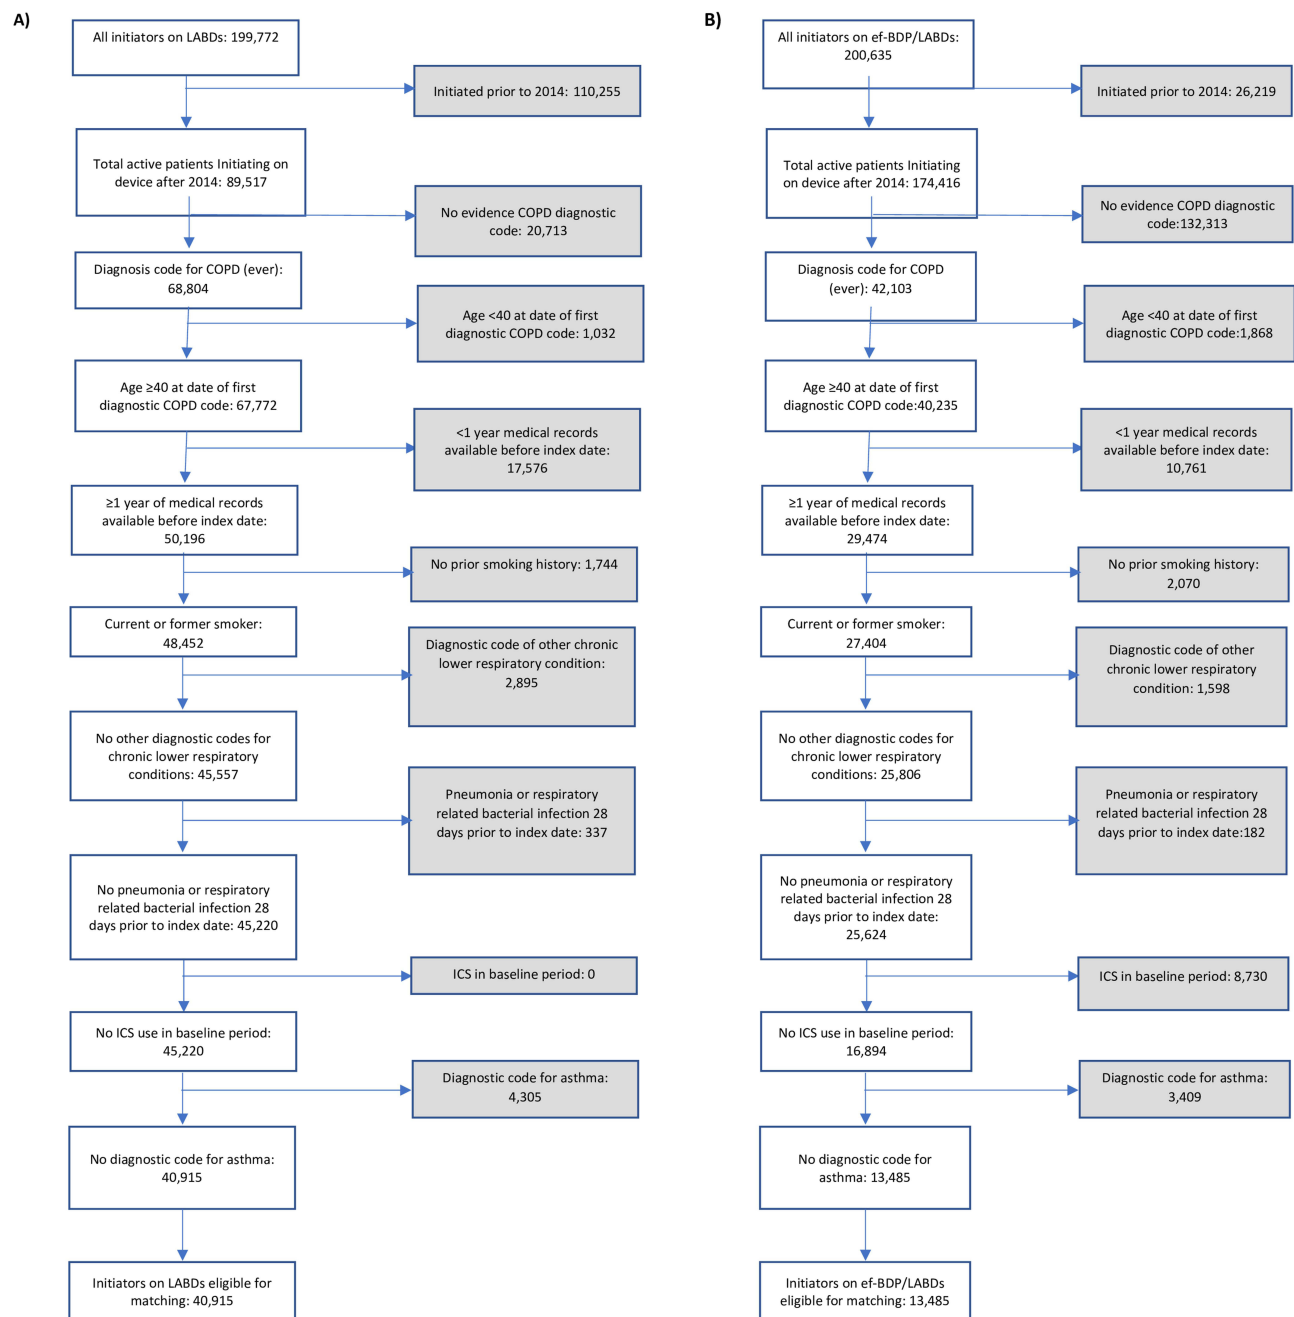

Figure 1 (A) Flow diagrams for patients commencing (A) LABD or (B) ef-BDP/LABD therapy and their eligibility for matching. (B) Flow diagrams for patients commencing (A) LABD or (B) ef-BDP/LABD therapy and their eligibility for matching.

Abbreviations: COPD, chronic obstructive pulmonary disease; ef-BDP/LABD, extrafine beclometasone / long-acting bronchodilators; ICS, inhaled corticosteroids; LABD, long-acting bronchodilators.

Primary Outcomes

In comparison to LABD, initiation of ef-BDP/LABD was not associated with any significant increase in the hazard risk (HR) and 95% confidence interval of developing a sensitive definition pneumonia, for either matched (HR 0.89 (0.78–1.02), $P = 0.08$) or unmatched populations (HR 1.09 (0.98–1.21), $P = 0.11$) (Table 2 and Figure 4). The probability of remaining pneumonia free 1 year after commencement of ef-BDP/LABD was 98.4%, which was comparable to LABD at 97.7% (Figure 5). Similar results were also observed 6 years after the commencement of ef-BDP/LABD (90.3%) and LABD (90.0%).

Table 1 Demographic Features of Unmatched and Matched Populations Commencing Formulations Containing Extrafine Beclometasone/Long-Acting Bronchodilators (Ef-BDP/LABD) or Long-Acting Bronchodilators (LABD)

	5, n (%)	421 (4.0)	476 (1.6)	269 (2.9)	295 (3.2)

Abbreviations: BMI, body mass index; extrafine beclometasone/long-acting bronchodilators (ef-BDP/LABD); ef-FDC-B, extrafine fixed dose combination beclometasone; FEV₁, Forced Expiratory Volume 1; fp-FDC-F, fine-particle fixed dose fluticasone; GOLD, global initiative for chronic obstructive lung disease; ICS, inhaled corticosteroid; LABA, long acting beta agonist; LABD, long-acting bronchodilators; LAMA, long acting muscarinic antagonist; mMRC, modified medical research council; SABA, short acting beta agonist; SAMA, short acting muscarinic antagonists; SD, standard deviation.

Similarly, the commencement of ef-BDP/LABD was not associated with any significant increase in the risk of developing a specific definition of pneumonia in the matched population 0.91 (0.78–1.05), $P = 0.18$, but with a marginal significant increase in the unmatched population 1.14 (1.02–1.28), $P = 0.02$ when compared to LABD. There was no significant variation in the survival function for remaining pneumonia free, from a specific definition pneumonia, one to six-years after the commencement of either ef-BDP/LABD or LABD in the propensity matched as-treated population (ef-BDP pneumonia free 98.6% at 1 year and 91.1% at 6 years; LABD pneumonia free 98.0% at 1 year and 91.5% at 6 years (Figure 6). The criterion for non-inferiority for those patients commencing ef-BDP/LABD therapy was achieved for both sensitive and specific definitions with the upper 95% CI boundaries below 1.15 (Table 2 and Figure 4).

Secondary Outcomes

The initiation of ef-BDP/LABD was associated with a reduced risk of developing LRTI in the matched population 0.76 (0.72–0.79), $P < 0.001$, when compared to LABD (Table 2). The probability of remaining free from LRTI after the commencement of ef-BDP/LABD was 82.2%, compared to 80.1% after the commencement of LABD in the propensity matched cohort and remained significant after six years ($P < 0.001$). (Figure 7).

Exploratory Outcomes

Assessment of exploratory outcomes indicates ef-BDP/LABD use was associated with a significant reduced risk of requiring antibiotic prescriptions, developing exacerbations, and having a primary care recorded hospitalisation (all $p < 0.05$) in the matched population, when compared to LABD alone (Table 2). The use of ef-BDP/LABD was not associated with a different risk of pneumonia-related hospitalisations for matched 0.90 (0.75–1.07), $P = 0.23$ and unmatched 0.90 (0.75–1.07), $P = 0.23$ populations (Table 2).

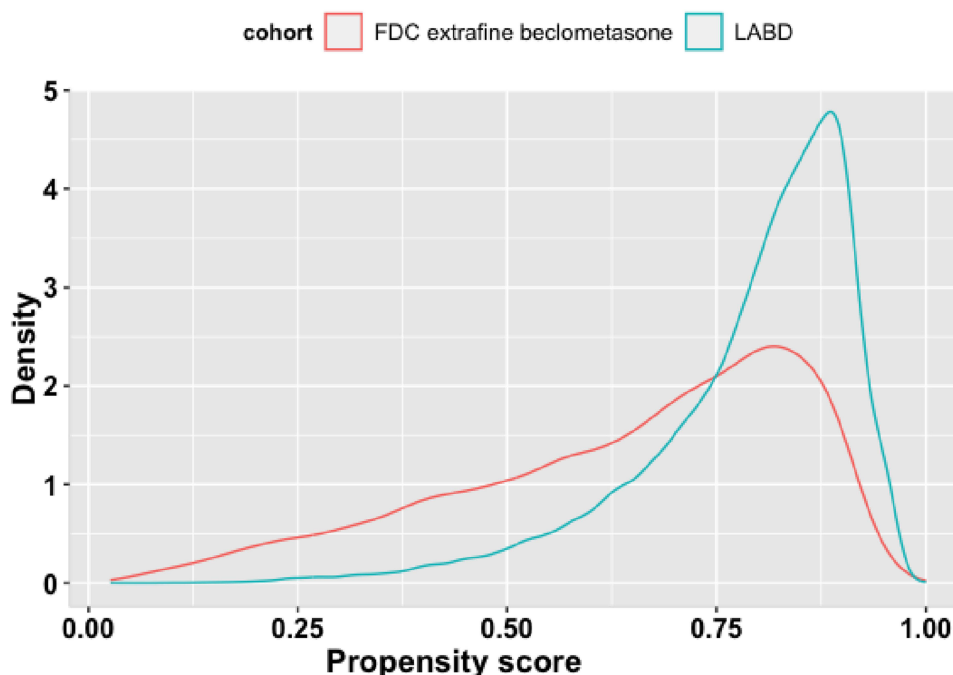

Figure 2 Density plots showing the distribution of propensity scores for patients treated with formulations containing extrafine beclomethasone/long-acting bronchodilators (ef-BDP/LABD) or long-acting bronchodilators (LABD) without ICS.

Notes: Density plots showing the distribution of propensity scores for patients treated with extrafine particle fixed dose beclomethasone (ef-FDC-BDP) and LABD. The propensity score represents the estimated probability that each patient is assigned to fp-FDC-F treatment, based on their baseline characteristics (with possible values ranging from 0 to 1). A rug plot is shown along the x-axis, with a circle representing the propensity score for each patient, providing a compact visualisation of the range of propensity score values for each treatment (range of propensity scores for LABD: 0.09–0.94; range of propensity scores for LABD: 0.12–0.96).

Abbreviations: LABD, long-acting bronchodilators; FDC, Fixed Dose Combination.

Discussion

Compared with LABD, the initiation of ICS/LABD formulations containing extrafine beclomethasone was not associated with a significantly increased risk of developing pneumonia, and the criterion for non-inferiority was achieved for both the sensitive and specific definitions of pneumonia. New users of beclomethasone-containing dual or triple therapies had a statistically significant reduced risk of developing lower respiratory tract infections, requiring prescriptions for antibiotics, developing exacerbations, and having a period of hospitalisation recorded within their primary care records. Rates of our study more sensitive definition of pneumonia in both the ef-BDP/LABD and LABD were lower than anticipated, but comparable to prior studies.

Our real-world results are in line with the results of the TRIBUTE RCT.³⁴ Conversely, both the TRINITY and FORWARD RCTs reported the use of extrafine formulations containing beclomethasone to be associated with an increased risk of pneumonia when compared to LABD without ICS.^{31,32} Notably, assessing ICS use and its associated risk of pneumonia was not a primary objective of the TRINITY and FORWARD studies; rather it was reported as an adverse event and had an effect size, measured as an unadjusted absolute risk difference, of 1% and 2% respectively.^{31,32} In comparison to the FORWARD study which had a one year follow up, the effect size (adjusted absolute risk difference) for ef-BDP use when compared to LABD in the present investigation over the same period of time was -0.4% and -0.3% for our study sensitive and specific definitions of pneumonia, respectively. Further, differences in pneumonia rates between ef-BDP containing ICS/LABD and the LABD in these three RCTs highlight the variability of capturing this event as a TEAE.

Differences in the study populations and how pneumonia was defined may help explain the variation in effects and effect sizes.⁴⁰

The current study was designed to more closely represent what is observed in broader COPD populations, rather than those included in RCTs. In doing so, observing that extrafine beclomethasone formulations do not significantly alter the

risk of pneumonia, and in fact an association with a reduced risk of developing lower-respiratory tract infections was observed when compared to LABD alone, suggesting variations in the risk profile of ICS drugs when used for the management of a wider and more diverse clinical population of COPD patients. Potential effect modifiers may explain a reduced risk profile of ef beclometasone, including particle size, potency and dose used.

In relation to particle size, extrafine formulations of ICS more easily enter the small airways than formulations containing larger particles.⁴¹ This allows to use lower doses of extrafine formulations to mediate the same desired clinical effect when compared to suspensions with larger particle size,⁴¹ which may be advantageous when trying to minimise adverse effects. Other factors including lipophilicity, which influences retention in the airways, have also been suggested.^{29,42} Collectively, these observations may explain why ef-BDP did not significantly increase the risk of pneumonia when administered with LABDs to COPD patients in the present study.

As reported in the current investigation, the one-year Kaplan-Meier estimates for cumulative incidence of our study sensitive definition of pneumonia for both ef-BDP/LABD and LABD groups was close to 2%. This rate is in line with estimates reported in the TRINITY and FORWARD clinical trials, but is much lower than the annual rate seen in IMPACT.^{31–33} It is possible this lower rate of pneumonia observed in the present investigation is attributed to the level of COPD severity within the study population. In comparison to IMPACT, LABD patients in the present investigation had milder COPD, as evidenced by higher FEV₁% values and lower exacerbation rates, and the matched ef-BDP/LABD patients also had milder symptoms.

A key strength of the current investigation was the design which allowed for direct assessment and quantification of mostly unbiased risk associated with ef-BDP/LABD use when compared to LABD by propensity-matching, minimizing confounding. Additionally, a robust study population with available medical records over an extensive period serves as additional strength. The median time for data collection in a patient's record in the database was 13 years, and this

lengthy follow-up period allowed for sufficient assessment of pneumonia risk associated with extrafine beclometasone containing ICS/LABD formulations. The presentation of as-treated data is also important as it considered the actual period during which patients were at-risk of pneumonia and other respiratory related adverse effects of their treatment. Finally, use of a propensity score matching process with a calliper helped minimise residual confounding bias by ensuring a high level of balance between the groups across a wide range of measured covariates.

With respect to limitations, it should be noted that the current investigation does not allow for exploration of how pneumonia risk varies with the use of mono or dual LABDs in both the ICS/LABD or LABD in isolation groups. Time to event analysis was also only conducted for the first event, meaning any subsequent pneumonia event/s were not captured in the current analysis. The exploratory analysis of time to event for acute OCS use and antibiotics prescriptions were also not qualified specifically for COPD exacerbations and pneumonia respectively. Additionally, COPD patients who had no smoking history were excluded from this study, as they have been shown to have milder COPD symptoms, less inflammation and fewer comorbidities than current or former smokers.⁴³ Finally, this study does not provide direct comparisons between different ICS-containing fixed-dose combinations, or different dosages, and further research on the impact of different ICS on the lung microbiome and immune system are needed to further shed light on these intra-class differences.

Conclusion

In comparison to LABD, commencement of ef-BDP/LABD formulations was not associated with a significant increased risk of developing pneumonia in a large propensity matched real-world cohort of COPD patients, and therefore non-inferiority vs LABD was achieved; this effect at 1 year was sustained up to 6 years of observation. New users of ef-BDP/LABD also had a significantly reduced risk of lower-respiratory tract infections compared to LABD therapy. Collectively, this suggests that extrafine beclometasone formulations for the management of COPD are not associated with an increased risk of pneumonia in a diverse real-world clinical population, contrary to what has been reported in some randomised controlled trials. Notably, this could be attributed to molecular potency, lung deposition and formulation characteristics of extrafine beclometasone, as well as differences in the clinical features of the populations involved.

Ethics Approval

The study protocol was established prior to data extraction, in accordance with the criteria for the European Network Centers for Pharmacoepidemiology and Pharmacovigilance (ENCePP) and follows the ENCePP code of conduct (2014). Registration of the study with the European Union electronic Register of Post-Authorization studies was also undertaken (EUPAS35439). As noted, the dataset was derived from the OPCR, which has ethical approval from the National Health Service Research Authority to hold and process anonymised research data (Research Ethics Committee reference: 15/EM/0150). Approval for this study was granted by the Anonymised Data Ethics Protocols and Transparency (ADEPT) committee – the independent scientific advisory committee for the OPCR (ADEPT0820). The authors do not have permission to give public access to the study dataset; requests to access OPCR can be made via the OPCR website (<https://opcrd.co.uk/our-database/data-requests/>) or via the enquiries email info@opcrd.co.uk.

Pragmatic and Observational Research

Dovepress

Publish your work in this journal

Pragmatic and Observational Research is an international, peer-reviewed, open access journal that publishes data from studies designed to reflect more closely medical interventions in real-world clinical practice compared with classical randomized controlled trials (RCTs). The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
